

Perovskite gains most where sunlight is weakest

A physics-consistent twin shows perovskite's edge over silicon is a temperature effect — so it inverts in geography

1 Why: a temperature effect

2 So it inverts: Southwest > Northwest

3 Survives every test

[v] device mechanism
advantage vs temperature, $r = +0.93$

[v] 5 adversarial scenarios
bifacial / mount / thermal:
 $r = -0.46$ to -0.63 (all hold)

[v] 0.1 deg grid, 95k China cells
 $r = -0.54$

4 Policy: site by physics, not by sunshine

Today China builds PV where perovskite is worth least: the top-advantage provinces (Southwest) hold only 22% of capacity, the lowest ~34%.
Deploy perovskite in the hot, cloudy Southwest — not the sunny Northwest 'desert-base' that current siting targets.
